Case report on the coincidence of retroperitoneal dedifferentiated giant liposarcoma and renal papillary cell carcinoma

Retroperitoneal dev dediferansiye liposarkom ve renal papiller hücreli karsinomun birlikte görüldüğü olgu sunumu

ABSTRACT

The most common histological type of retroperitoneal sarcomas is liposarcoma. Renal papillary cancers account for approximately 10% of all known renal cell cancers and nephrectomy is the preferred choice for the treatment in suitable cases. In this report, we presented a concurrence of giant retroperitoneal liposarcoma and renal papillary cancer in a 61-year-old male patient. He was referred to our clinic with complaints of abdominal distension and pain. Computed tomography (CT) scan, magnetic resonance imaging (MRI) and positron emission tomography-computed tomography (PET-CT) revealed a giant mass filling intraabdominal and retroperitoneal space, approximately 50x30 cm in size and also a separate mass which is 6x8 cm in size in the upper pole of the left kidney. The giant mass was excised in two separate pieces. After frozen section procedure, nephrectomy was performed for mass arising from the left kidney. Histopathological analysis of the large masses, revealed dedifferentiated liposarcoma and renal papillary cellular cancer in the abdomen and left kidney, respectively.

In conclusion, a second primary tumor can be seen in patients with giant retroperitoneal liposarcoma and coincidence of these tumors must be determined in the preoperative period for appropriate treatment.

Keywords: Retroperitoneum, Liposarcoma, Renal papillary cancer

Introduction

Retroperitoneal sarcomas are rare tumors that account for 15% of all soft tissue sarcomas. The most common histological type is liposarcoma (41%) [1]. Because of its characteristic deep location, retroperitoneal liposarcomas are difficult to be diagnosed. While intra-abdominal mass effects are the most common symptoms present in 80% of patients, pain is the second common symptom [2]. Computed tomography (CT) scan, magnetic resonance imaging (MRI) and positron emission tomography-computed tomography (PET-CT) are diagnostic examinations with unique findings [3]. The gold standard for the treatment is surgery [1]. On the other hand, renal papillary cancer (RPC) accounts for 10-15% of all types of renal cell cancers and it is the second common type. The primary treatment of RPC is nephrectomy [4].
Because of increasing number of PET-CT examinations in the recent years, a significant higher incidence of second primary cancers has been observed. A second primary tumor on the left kidney with retroperitoneal giant liposarcoma has been simultaneously observed in our patient in PET-CT examination for staging. After surgery, in pathologic specimens, renal papillary cancer was diagnosed with dedifferentiated giant liposarcoma.

**Case Report**

A 61-year-old male patient who had previously been examined in another medical center with the complaints of abdominal discomfort and pain admitted to our centre. CT and subsequent PET-CT scan revealed a mass in the abdomen corresponding to a liposarcoma which has heterogeneous, calcified and solid components with fat density. It was approximately 50x30 cm in size expanding from all retroperitoneal space to the anterior abdominal wall (Fig.1a). Also, another mass, measured about 6x8 cm, was seen in the upper pole of left kidney (Fig.1b).

Percutaneous core-biopsy result of the giant mass was liposarcoma. In the surgical exploration, a giant mass filling the whole retroperitoneum, covering both kidneys and invading right colon was seen. This mass was removed as two separate pieces which were approximately 40x35 cm and 30x20 cm in size. Right hemicolectomy was performed with the right kidney preservation (Fig.2a-2b).

Frozen section biopsy analysis of the tumor in the left kidney revealed malignancy. Left kidney nephrectomy was performed. Two pieces of giant soft tissue masses which were 14 kg in total were defined as dedifferentiated liposarcomas in histopathological examination (Fig.3). Left nephrectomy material, measured 4x3 cm, was reported as renal papillary cell cancer (Fig.4).

The patient was discharged without any complaint. Six months after the first surgery, follow-up CT scan showed a 7x5 cm intra-abdominal mass in the periumbilical region. It was accepted as recurrence and the patient was operated again.
Discussion

With a rate of 41%, liposarcoma is the most common histological type of retroperitoneal sarcomas [1]. This is followed by leiomyosarcoma (28%), malignant fibrous histiocytoma (7%) and fibrosarcoma (6%). Liposarcomas originate from mesoderm and are differentiated from the adipose tissues [5]. Liposarcomas account for 10-14% of all soft tissue sarcomas and 85% of them are malignant [6]. They are seen more frequently in males and 5th and 6th decades of life [2,7]. Our patient is male and 61 years old.

The well-differentiated liposarcoma has the best clinical course. The worst clinical outcome is defined in the poor differentiated liposarcomas. Dedifferentiated liposarcoma is defined as “to express the poorly differentiated sarcoma adjacent to well-differentiated liposarcoma”. Dedifferentiated liposarcoma is a high-grade sarcoma with more malignant and aggressive course seen in older ages [3]. The vast majority are located in the retroperitoneum. Histological type of the tumor, its location, age older than 50, tumors larger than 10 cm, microscopically positive surgical margins and presence of local recurrence are among poor prognostic criterias [1]. Local recurrence and distant metastases are 41% and 17%, respectively. Distant metastases can be seen in the lungs, liver, brain, and bones.

Because of their location, the retroperitoneal sarcomas are generally asymptomatic. The most common symptoms are abdominal pain, abdominal swelling or palpable mass [2]. Our patient was admitted to our hospital with the complaints of swelling and pain in the abdomen. All his symptoms occurred in the last few months.

Computed tomography, MRI, and PET-CT are consecutive examinations in diagnosis in order to define tumor size, its localization and/or in determining metastatic lesions [3]. In our study, besides the CT scan, PET-CT imaging was also performed in our hospital. PET-CT findings showed, hypometabolic parts in some areas of the tumor and hypermetabolic parts in other areas, and various SUV-max values in different areas showed different biological properties. Histopathological examination results of different differentiated areas of the tumor, supported the PET-CT scan findings.

Liposarcomas are slow-growing tumors. Because of retroperitoneal location they show symptoms in a late period. At the time of diagnosis, 20% of these tumors are detected when they become larger than 10 cm, with an average diameter of 20-25 cm and an average weight of 15-20 kg [1,6]. Only, a few cases larger than these sizes have been published in the literature [2,6]. In our case, a giant liposarcoma with an approximate total size of 50x30 cm was excised in two pieces - one measured 41x35x15 cm in size and the other measured as 33x21x12 cm. The total weight of the tumor was 14 kg.

Liposarcomas are chemo-resistant tumors. As the toxic effects are widely observed in the extensive implementation of radiation therapy, surgery is the gold standard for the treatment [1,7]. In surgery, in order to achieve tumor-free surgical margins, kidneys, ureters or colon can be resected if any of them are invaded by the tumor. In our case, the tumor has encased the right
kidney and the ascending colon. As a left nephrectomy operation was performed, the right kidney was protected by dissecting only the tumor, and the giant masses were removed with right hemicolectomy.

Like liposarcomas, renal papillary cancers are also seen more frequently in males and in the 6th and 7th decades of life [4]. They are also tumors that are resistant to chemotherapy and radiation therapy, that is why they are treated with nephrectomy [4,8]. In our case, frozen section technique was also applied for kidney tumor. After the malignant result of frozen section, left nephrectomy was performed.

Conclusion

Coincidence of liposarcoma and renal cancer is quite rare in the literature [8]. It should be considered that in patients with retroperitoneal giant liposarcoma, the second primary tumors such as renal cell cancers might also be seen. Detection of coincidence in pre-operative examinations can allow simultaneous treatment in surgery.
